Abstract— Someone planning to remix a song would like to have segmented stem tracks at their disposal; that is, isolated instances of the loops and sounds that were used to compose the original song. We present Unmixer, a web service that will analyze and extract loops from any audio uploaded by a user (see Fig. 1). The loops are presented in an interface that allows them to be immediately remixed, and if users upload multiple tracks, they can create mash-ups with the loops, which are automatically matched in tempo.

I. PROJECT DETAILS

To analyze the audio, we adapt a method of source separation that we recently proposed [1], in which a 2D spectrogram is split at each downbeat and stacked into a 3D “spectral cube”, allowing us to model periodic repetitions. We estimate the nonnegative Tucker decomposition, which describes the signal very naturally as the product of a set of sounds, rhythms, and loop activations, the latter directly estimating the compositional layout of the estimated loops (see Fig. 2).

To reduce the redundancy of some loops, we propose an extra factorization step with a sparseness constraint and demonstrate (in a test using synthesized pieces) that it improves the source separation result. We also propose a method for selecting the best instances of the extracted loops (maximizing their loudness and minimizing cross-talk from other loops) and demonstrate its effectiveness in an evaluation. Both of these improvements are incorporated into the back end of the interface.
